### Supporting Information

**ABSTRACT:** Cytochrome P450 (P450) 4A11 is the only functionally active subfamily 4A P450 in humans. P450 4A11 catalyzes mainly  $\omega$ -hydroxylation of fatty acids in liver and kidney; this process is not a major degradative pathway, but at least one product, 20-hydroxyeicosatetraenoic acid, has important signaling properties. We studied catalysis by P450 4A11 and the issue of rate-limiting steps using lauric acid  $\omega$ -hydroxylation, a prototypic substrate for this enzyme. Some individual reaction steps were studied using pre-steady-state kinetic approaches. Substrate and product binding and release were much faster than overall rates of catalysis. Reduction of ferric P450 4A11 (to ferrous) was rapid and not rate-limiting. Deuterium kinetic isotope effect (KIE) experiments yielded low but reproducible values (1.2–2) for 12-hydroxylation with 12-<sup>2</sup>H-substituted lauric acid. However, considerable “metabolic switching” to 11-hydroxylation was observed with [12-<sup>2</sup>H<sub>3</sub>]lauric acid. Analysis of switching results [Jones, J. P., et al. (1986) *J. Am. Chem. Soc.* 108, 7074–7078] and the use of tritium KIE analysis with [12-<sup>3</sup>H]lauric acid [Northrop, D. B. (1987) *Methods Enzymol.* 87, 607–625] both indicated a high intrinsic KIE (>10). Cytochrome *b*<sub>5</sub> (*b*<sub>5</sub>) stimulated steady-state lauric acid  $\omega$ -hydroxylation ~2-fold; the apoprotein was ineffective, indicating that electron transfer is involved in the *b*<sub>5</sub> enhancement. The rate of *b*<sub>5</sub> reoxidation was increased in the presence of ferrous P450 mixed with O<sub>2</sub>. Collectively, the results indicate that both the transfer of an electron to the ferrous-O<sub>2</sub> complex and C–H bond-breaking limit the rate of P450 4A11  $\omega$ -oxidation.

Cytochrome P450 (P450) subfamily 4A enzymes are historically important and also of considerable interest because of the biological activity of some of their products. Lauric acid 12-hydroxylation was the assay used in the first successful P450 solubilization/separation/reconstitution studies of Lu and Coon with rabbit liver microsomes.<sup>1</sup> Although what is known today as (rabbit) P450 2B4 was of the most interest in the subsequent efforts to first purify a mammalian P450,<sup>2</sup> our current knowledge base of catalytic specificity<sup>3</sup> would suggest that a P450 subfamily 4A enzyme might have been the object of the original study.<sup>1</sup> P450 4A subfamily enzymes have been studied extensively in several animal models and exhibit activity with a number of lipid substrates.<sup>4–11</sup> In humans, P450 4A11 appears to be the only subfamily 4A P450 enzyme, with the (CYP) 4A22 gene not encoding an active protein.<sup>12</sup>

The subfamily 4A P450s have several general properties in common. They use fatty acids and other long chain compounds as substrates.<sup>13</sup> Part of the heme becomes covalently attached in several, but this phenomenon does not appear to be linked to catalytic activity.<sup>14,15</sup> In contrast to several other P450s that oxidize fatty acids, many of the subfamily 4A P450s selectively catalyze  $\omega$ -hydroxylation because of steric restriction in the active site.<sup>16</sup> No subfamily 4A P450 crystal structures are yet available, but some insight into structural features has been gleaned from site-directed mutagenesis.<sup>16,17</sup>

One of the more interesting translational aspects of (human) P450 4A11 research is the association of a single-nucleotide polymorphism (*rs1126742*) with an increased level of salt-sensitive hypertension.<sup>18</sup> The polymorphism has been associated with a 40% attenuation of arachidonic acid  $\omega$ -hydroxylation activity because of the F434S amino acid substitution associated with the polymorphism.<sup>18</sup> The reaction product, 20-OH-eicosatetraenoic acid, has been shown to have both hypertensive and hypotensive properties in animal models.<sup>19</sup> The same reaction is also catalyzed by some human subfamily 4F P450s.<sup>3,10</sup>

Although there is considerable interest in P450 4A11 because of the biological properties of some of its products,<sup>19–21</sup> the amount of biochemical information about it is limited.<sup>13,17,18,22</sup> With recombinant P450 4A11 and the prototypic reaction of lauric acid 12-hydroxylation, varying (respective) *k*<sub>cat</sub> and *K*<sub>m</sub> values of 15 min<sup>–1</sup> and 57  $\mu$ M,<sup>22</sup> 38 min<sup>–1</sup> and 200  $\mu$ M,<sup>17</sup> and 20 min<sup>–1</sup> and 11  $\mu$ M,<sup>18</sup> respectively, have all been reported. Maximal activity is achieved in the presence of cytochrome *b*<sub>5</sub> (*b*<sub>5</sub>).<sup>17</sup> Kawashima et al.<sup>22</sup> reported a lack of detectable arachidonic acid  $\omega$ -hydroxylation activity by recombinant

P450 4A11, but Gainer et al.<sup>18</sup> did find activity ( $k_{\text{cat}} = 2.2 \text{ min}^{-1}$ ), as we have in our own laboratory (with parameters similar to those of Gainer et al.,<sup>22</sup> unpublished results).

Despite the interest in P450 4A11 and its catalytic activities, very little is known about which step(s) in the catalytic cycle (Figure 1) limits activity. Studies with other human and

**Figure 1.** General catalytic P450 scheme.

experimental animal P450s have shown that steps 2, 4, 7, and 9 can all be rate-limiting in different reactions.<sup>23,24</sup> We utilized the approach of analyzing rates of individual reaction steps and measuring KIEs to kinetic models to determine which steps might be limiting, as has been done with several other P450s.<sup>23,25–27</sup> We conclude that major factors limiting the rate of lauric acid 12-hydroxylation are the rate of transfer of an electron from  $b_5$  and the rate of C–H bond breaking. The intrinsic KIE was attenuated in steady-state kinetic measurements because it is not the only rate-limiting step.

## EXPERIMENTAL PROCEDURES

**Chemicals.** Lauric (dodecanoic) acid ( $d_0$ ,  $d_3$ , and  $d_{23}$ ) and 12-OH lauric acid were purchased from Sigma-Aldrich and used without further purification. Lauric acid labeled with only one isotopic atom ( $d_1$  or  $t_1$ ) was prepared by the reaction of 12-bromododecanoic acid with  $\text{NaB}^2\text{H}_4$  or  $\text{NaB}^3\text{H}_4$ , respectively, in  $(\text{CH}_3)_2\text{SO}$ .<sup>28</sup> The  $d_1$  ( $^2\text{H}$ ) reaction was conducted on a 10 mmol scale and the  $t_1$  ( $^3\text{H}$ ) reaction on a 0.10 mmol scale (with 5 mCi of  $\text{NaB}^3\text{H}_4$ , American Radiolabeled Chemicals, St. Louis, MO), and the product was recrystallized from a  $\text{C}_2\text{H}_5\text{OH}/\text{H}_2\text{O}$  mixture. The yields for the two reactions were 78 and 87%, respectively; the atomic excess of  $d_1$ -lauric acid was 90%, and the specific radioactivity of  $t_1$ -lauric acid was 0.23 mCi/mmol. [ $1\text{-}^{14}\text{C}$ ]Lauric acid was purchased from American Radiolabeled Chemicals. Other chemicals were of the highest commercially available grade.

**Enzymes.** P450 4A11 was expressed in *Escherichia coli* from a pCW4A11 plasmid including a  $(\text{His})_6$  tag at the C-terminus. Expression and purification of P450 4A11 were conducted as previously described, with some modifications.<sup>18,29</sup> Briefly, the *E. coli* strain transformed with the pCW(Or $^+$ ) vector was inoculated into Terrific Broth (TB) medium containing 100  $\mu\text{g mL}^{-1}$  ampicillin and 1.0 mM isopropyl  $\beta$ -D-1-thiogalactopyranoside. The expression cultures (1 L) were grown at 37 °C for

3 h and then at 28 °C while being shaken at 200 rpm for 48 h in 2.8 L Fernbach flasks. The bacterial inner membrane fraction containing P450 4A11 was isolated and prepared from TB expression cultures using ultracentrifugation ( $10^5g$  for 60 min). The prepared membrane fraction was solubilized overnight at 4 °C in 100 mM potassium phosphate buffer (pH 7.4) containing 20% (v/v) glycerol, 0.1 mM EDTA, 10 mM  $\beta$ -mercaptoethanol, and 2% (w/v) 3-[(3-cholamidopropyl)dimethylammonio]-2-hydroxy-1-propanesulfonate (CHAPS) (Anatrace, Maumee, OH). The solubilized fraction, following ultracentrifugation ( $10^5g$  for 60 min), was then loaded onto a  $\text{Ni}^{2+}$ -nitrilotriacetate column (Qiagen, Valencia, CA), and the proteins were eluted with a buffer containing 300 mM imidazole. The eluted fractions containing P450 4A11 were subsequently dialyzed at 4 °C against 100 mM potassium phosphate buffer (pH 7.4) containing 20% (v/v) glycerol and 0.1 mM EDTA. The protein preparations were >90% pure as judged by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (data not presented).

Rat NADPH-P450 reductase<sup>30</sup> and human  $b_5$ <sup>31</sup> were expressed in *E. coli* and purified as described previously. Apo- $b_5$  was prepared from  $b_5$  by acid-acetone extraction as described previously.<sup>32,33</sup> *Pseudomonas* sp. protocatechuate dioxygenase was purchased from Sigma-Aldrich. Microsomes were prepared from a mixture of 10 individual human liver samples (mixed on the basis of equal mass) using a general differential centrifugation procedure.<sup>34</sup> The source of the human liver tissue was the Nashville Regional Organ Procurement Agency (approved by the Institutional Review Board).

**Enzymatic Assays.** Typical incubations included 0.2  $\mu\text{M}$  P450 4A11, 0.4  $\mu\text{M}$  NADPH-P450 reductase, 0.4  $\mu\text{M}$   $b_5$ , 150  $\mu\text{M}$  L- $\alpha$ -dilauroyl-*sn*-glycero-3-phosphocholine, 100 mM potassium phosphate buffer (pH 7.4), 1 mM dithiothreitol, and the indicated concentration of lauric acid (usually added as an aqueous solution of sodium laurate) in a final volume of 0.50 mL.  $b_5$  was included because it stimulated the catalytic activity (Figure 2). Following temperature equilibration to 37 °C for 5

**Figure 2.** Effect of  $b_5$  on lauric acid 12-hydroxylation activity of P450 4A11. Products were measured using the GC method, using a substrate concentration of 100  $\mu\text{M}$ .

min, reactions were initiated by the addition of an NADPH-regenerating system consisting of 0.5 mM  $\text{NADP}^+$ , 10 mM glucose 6-phosphate, and 1 IU  $\text{mL}^{-1}$  yeast glucose 6-phosphate dehydrogenase.<sup>34</sup> Reactions generally proceeded at 37 °C for 15 min and were terminated with 1.0 mL of  $\text{CH}_2\text{Cl}_2$  and the mixtures centrifuged ( $10^3g$  for 10 min). A 0.8 mL aliquot of the  $\text{CH}_2\text{Cl}_2$  layer (lower phase) was transferred to a clean tube. An additional 1.0 mL of  $\text{CH}_2\text{Cl}_2$  was added to the supernatant to

extract the products, followed by centrifugation at  $10^3g$ . The organic layers were combined, and the solvent was removed under a  $N_2$  stream.

For GC–MS analysis, the dried extracts were converted to trimethylsilyl ethers by incubation with 50  $\mu$ L of  $N,O$ -bis(trimethylsilyl)trifluoroacetamide containing trimethylchlorosilane [1% (v/v)] at 75 °C for 20 min [procedure based on BSTFA product specification/typical procedure provided by the supplier (Supelco/Sigma-Aldrich) ([https://www.sigmaaldrich.com/content/dam/sigma-aldrich/docs/Supelco/Product\\_Information\\_Sheet/4746.pdf](https://www.sigmaaldrich.com/content/dam/sigma-aldrich/docs/Supelco/Product_Information_Sheet/4746.pdf))]. The derivatized samples were allowed to cool, mixed using a vortex device, and transferred to sealed Teflon-capped glass vials for autoinjection on a Shimadzu GC-2010 gas chromatograph, using an Rtx-5 column [5% diphenyl/95% dimethylpolysiloxane capillary (w/w)] [30 m  $\times$  0.32 mm (inside diameter)  $\times$  0.25  $\mu$ m (film thickness)], as previously described.<sup>35</sup> 10-Hydroxydecanoic acid was used as an internal standard. Hydroxylated products of lauric acid at the  $\omega$  and  $\omega-1$  positions were identified by their characteristic mass fragmentation patterns. Turnover numbers of the hydroxylation of lauric acid at the  $\omega$  and  $\omega-1$  positions by P450 4A11 were determined by a GC flame ionization detector (Shimadzu GC2010 instrument with a flame ionization detector). The distribution of products was based on the relative peak areas of the GC chromatograms (using 10-hydroxydecanoic acid as an internal standard). Similar rates were observed for GC–MS and the radioactive assays (*vide infra*).

In the case of reactions with human liver microsomes, the microsomes (1 mg of protein  $mL^{-1}$ ) were used directly with the lauric acid substrates and the NADPH-generating system.

With  $1-^{14}C$ -labeled lauric acid as a substrate, the dried extracts were dissolved in 100  $\mu$ L of  $CH_3OH$  and then aliquots were analyzed on a reversed-phase (octadecylsilane,  $C_{18}$ ) high-performance liquid chromatography (HPLC) column [5  $\mu$ m, 2.1 mm  $\times$  100 mm (Waters, Milford, MA)] coupled with a radioisotope detector (IN/US Systems  $\beta$ -RAM, Tampa, FL). Reaction products and substrate were eluted at a flow rate of 0.6  $mL\ min^{-1}$  using an increasing linear gradient of  $CH_3CN$  [including 0.1% (v/v)  $HCO_2H$ ] from 40 to 95% (v/v) over 30 min.

Steady-state kinetic results were fit to hyperbolic plots in GraphPad Prism (GraphPad Software, San Diego, CA) to determine  $k_{cat}$  and  $K_m$  values, plus the standard error (SE) [see also Kinetic Isotope Effects (KIEs) (*vide infra*)].

**Spectral Binding Titrations.** Purified P450 4A11 was diluted to 2.0  $\mu$ M in 0.10 M potassium phosphate buffer (pH 7.4), and binding spectra (350–500 nm) were recorded following subsequent additions of lauric acid or 12-OH lauric acid using an OLIS-Aminco DW2a spectrophotometer (Online Instrument Systems, Bogart, GA) as described previously.<sup>36,37</sup> The difference between the absorbance maximum and minimum was plotted versus the ligand concentration, and binding constants ( $K_d$ ) and the SE were estimated using GraphPad Prism, either using either a hyperbolic fit or a quadratic equation.

**Burst Kinetic Analysis.** Burst kinetic analysis of lauric acid hydroxylation was conducted in a quench-flow apparatus (model RQF-3, KinTek Corp., State College, PA) as previously described.<sup>38</sup> P450 4A11 (100 pmol) was reconstituted as described above and incubated in the presence of 100  $\mu$ M [ $1-^{14}C$ ]lauric acid, in a total volume of 20  $\mu$ L (per injection). Reactions were initiated by rapid mixing with 20  $\mu$ L of 10 mM

NADPH for a period of time ranging from 0.5 s to 4 min (as indicated) at 37 °C. Reactions were quenched with 300  $\mu$ L of 3% (w/v)  $CCl_3CO_2H$ , and the production of 12-OH lauric acid was quantitated using HPLC as described for steady-state reactions.

**Kinetic Isotope Effects (KIEs). Noncompetitive (intermolecular) KIEs.** Noncompetitive (intermolecular) KIEs were measured by comparing  $k_{cat}$  and  $K_m$  values measured with  $d_0$ -,  $d_3$ -, and  $d_{23}$ -lauric acid as substrates, using the conventions of Northrop<sup>39,40</sup> for expressing KIEs as  $^D V = ^H k_{cat} / ^D k_{cat}$  and  $^D (V/K) = (^H k_{cat} / ^H K_m) / (^D k_{cat} / ^D K_m)$ . KIEs were measured for both 12- and 11-hydroxylation.

**Competitive (intermolecular) KIEs.** Competitive (intermolecular) KIEs were examined by incubating the P450 4A11 system with an equimolar mixture of  $d_0$ - and  $d_{23}$ -lauric acid (100  $\mu$ M each) and measuring the relative amounts of 11- and 12-OH lauric acid formed by GC–MS. All four peaks were separated from each other because of the effect of the deuterium isotope on chromatography ( $t_R$  values of 16.5, 17.0, 19.0, and 19.4 min for  $d_{22}$ -11-OH lauric acid,  $d_0$ -11-OH lauric acid,  $d_{22}$ -12-OH lauric acid, and  $d_0$ -12-OH lauric acid, respectively).

**Intramolecular (competitive) Deuterium KIEs.** Intramolecular (competitive) deuterium KIEs were measured using  $d_1$ -lauric acid by LC–MS of the product 12-OH lauric acid, with the KIE being equal to 2 times the ratio of the intensities of the peaks at  $m/z$  215 ( $d_0$ ) and 216 ( $d_1$ ), after correction for  $^{13}C$  contributions<sup>41</sup> and the atomic excess of the  $d_1$  substrate. (The statistical factor of 2 was used because all lauric acid molecules in the reaction have two C–H bonds and one C–D bond at C-12.)

**An Intramolecular Tritium KIE.** An intramolecular tritium KIE was estimated using  $t_1$ -lauric acid (0.23 mCi  $mmol^{-1}$ ). Incubations with 100  $\mu$ M  $t_1$ -lauric acid were terminated after 15 min at 37 °C via the addition of 50  $\mu$ L of 6 M HCl. The aqueous reaction mixture was washed five times with 5 volumes of  $(C_2H_5)_2O$ . The radioactivity in the aqueous phase was measured using a liquid scintillation counter to estimate the amount of  $t$ - $H_2O$  released, and the  $(C_2H_5)_2O$  phase was evaporated to dryness. The residue was dissolved in  $CH_3CN$ , and an aliquot was used to measure tritium retention in 12-OH lauric acid by HPLC, using a radio-flow detector. The tritium KIE,  $^T(V/K)$ , was expressed as (disintegrations per minute of 12-OH lauric acid)/(disintegrations per minute of  $^3H_2O$ ) [because the protiated lauric acid is in a large excess of tritium and exchange of lauric acid with the enzyme is fast (*vide infra*), the competition is between the C–T bond and all of the C–H bonds in the lauric acid pool].

**Intrinsic Deuterium KIE ( $^Dk$ ).** The intrinsic deuterium KIE ( $^Dk$ ) was estimated from the deuterium and tritium KIE values using the approach of Northrop

$$[^D(V/K) - 1] / [^T(V/K) - 1] = (^Dk - 1) / (^Tk - 1)$$

and the appropriate tables.<sup>39</sup>

**Pre-Steady-State Kinetics. General.** Pre-steady-state kinetic analysis was conducted using an OLIS RSM-1000 instrument (Online Instrument Systems, Bogart, GA), in the rapid-scanning absorbance mode. Typical conditions used 1.24 mm slits and 600-line, 300 nm gratings. The temperature was 37 °C in the case of the measurements involving substrate and product binding and reduction of ferric P450 4A11.

**Substrate and Product Binding.** One syringe contained 2.0  $\mu$ M P450 4A11 in 100 mM potassium phosphate buffer (pH

7.4); the other syringe contained 100  $\mu\text{M}$  lauric acid or 12-OH lauric acid [added from a  $\text{CH}_3\text{OH}$  stock, final concentration of 0.5% (v/v)  $\text{CH}_3\text{OH}$  in 100 mM potassium phosphate buffer (pH 7.4)]. From the collected spectra, traces of  $\Delta A_{390}$  and  $\Delta A_{418}$  were fit to progress curves using DynaFit.<sup>42</sup>

**Reduction of Ferric P450 4A11.** Anaerobic tonometers<sup>43–45</sup> containing the reagents were used to load the stopped-flow syringes, which had been scoured overnight with a mixture of 1 mM protocatechuic acid and 0.03 unit  $\text{mL}^{-1}$  *Pseudomonas* sp. protocatechuate dioxygenase. The contents of the tonometers and syringes were under a CO atmosphere (positive pressure). One syringe contained 2  $\mu\text{M}$  P450 4A11, 2.4  $\mu\text{M}$  NADPH-P450 reductase, 60  $\mu\text{M}$  L- $\alpha$ -dilauroyl-sn-glycero-3-phosphocholine, and (when indicated) 200  $\mu\text{M}$  sodium laurate in 100 mM potassium phosphate buffer (pH 7.4). The other syringe contained 300  $\mu\text{M}$  NADPH in 100 mM potassium phosphate buffer. Both syringes contained an oxygen scrubbing system composed of 1 unit  $\text{mL}^{-1}$  protocatechuate dioxygenase and 0.25 mM protocatechuate. Plots of decreases in  $A_{390}$  were used in that the  $\Delta A_{450}$  rates were found to be slower because of an unexpectedly slow rate of CO binding (*vide infra*).

**Oxidation of  $b_5$ .**  $b_5$  (3.0  $\mu\text{M}$ ) in 200 mM Tris-acetate buffer containing 75  $\mu\text{M}$  L- $\alpha$ -dilauroyl-sn-glycero-3-phosphocholine, 10 mM EDTA, and 1  $\mu\text{M}$  5-deazaflavin<sup>46</sup> was photoreduced, as monitored in an OLIS-Cary 14 spectrophotometer (Online Instrument Systems) (2–3 min with a 500 W lamp positioned 15 cm away, immersed in a beaker of  $\text{H}_2\text{O}$  to prevent heating) and then transferred anaerobically to the stopped-flow spectrophotometer, where it was mixed with an equal volume of air-saturated 100 mM potassium phosphate buffer (pH 7.4). (The amines Tris and EDTA are sources of electrons.) Traces of  $\Delta A_{409}$  and  $\Delta A_{424}$  were fit to single-exponential plots.<sup>26</sup>

The experiment was repeated with 3.0  $\mu\text{M}$  P450 4A11 or a mixture of 3.0  $\mu\text{M}$  P450 4A11 and 3.0  $\mu\text{M}$   $b_5$ , in the presence of 1 mM tris(2-carboxyethyl)phosphine. Reduction was also conducted with 1  $\mu\text{M}$  5-deazaflavin and light (*vide supra*). Absorbance changes at 424 and 409 nm were used to estimate the rate of  $b_5$  oxidation upon reaction of  $\text{O}_2$  with ferrous P450 4A11.

**Other Assays.** NADPH oxidation rates were estimated by  $\Delta A_{340}$  measurements using 0.15  $\mu\text{M}$  NADPH (no generating system;  $\Delta \epsilon_{340} = 6.22 \text{ mM}^{-1} \text{ cm}^{-1}$ ). Formation of  $\text{H}_2\text{O}_2$  in reactions (500  $\mu\text{L}$ ) was initiated by adding 50  $\mu\text{L}$  of 10 mM NADPH and terminated with the addition of 1.0 mL of  $\text{CCl}_3\text{CO}_2\text{H}$  [3% (w/v)] after 2 min.  $\text{H}_2\text{O}_2$  concentrations were determined spectrophotometrically following reaction with ferroammonium sulfate and KSCN.<sup>47</sup> Reduction of  $\text{O}_2$  to  $\text{H}_2\text{O}$  was estimated by a subtractive method described previously.<sup>48</sup>

**Kinetic Fitting.** DynaFit<sup>42</sup> was used to fit some of the kinetic and binding data, e.g., substrate and product binding (Supporting Information).

## RESULTS

**Reaction Stoichiometry.** Lauric acid hydroxylation was demonstrated to be stimulated by  $b_5$  (Figure 2 and Figure S1 of the Supporting Information). A similar dependence has been found for  $\omega$ -hydroxylation of arachidonic acid with P450 4A11. Apo- $b_5$  was not effective (Figure S1 of the Supporting Information). Analysis of the overall reaction stoichiometry showed a pattern typical of mammalian P450s, with  $\sim 30\%$  of the electrons from NADPH used for hydroxylation of lauric acid (Table 1). All studies were conducted with 1 mM

**Table 1. Stoichiometry of P450 4A11 Lauric Acid Hydroxylation<sup>a</sup>**

| reaction                                    | rate ( $\text{min}^{-1}$ ) |
|---|----------------------------|
| NADPH oxidation                             | $28 \pm 1$                 |
| lauric acid 12-hydroxylation                | $8.6 \pm 0.5$              |
| $\text{H}_2\text{O}_2$ formation            | $13 \pm 3$                 |
| $\text{H}_2\text{O}$ formation <sup>b</sup> | $3 \pm 1$                  |

<sup>a</sup>Results are presented as means  $\pm$  the standard deviation (SD) (range) of duplicate assays. <sup>b</sup> $\text{H}_2\text{O}$  formation was determined by calculating the difference between NADPH oxidized and the sum of  $\text{H}_2\text{O}_2$  formation and products produced and then dividing by 2 (the SD for  $\text{H}_2\text{O}$  formation estimated from the square of sums of squares of individual SD values).<sup>48</sup>

dithiothreitol or tris(2-carboxyethyl)phosphine present, in that these reductants (or glutathione) were consistently found to enhance catalytic activity 2–3-fold. The remainder of the reducing equivalents were used to reduce  $\text{O}_2$  to  $\text{H}_2\text{O}_2$  and  $\text{H}_2\text{O}$ <sup>48</sup> (Table 1).

To define the steps that limit the overall rate, we analyzed the rates of individual steps.

**Substrate Binding (step 1 of Figure 1).** P450 4A11, as isolated, is in a mixed iron spin state, mostly in the low-spin form; second-derivative analysis<sup>49,50</sup> indicated  $\sim 10\%$  high-spin iron. Addition of lauric acid is associated with a shift in the spin state to high spin (“type I”).<sup>36</sup> The apparent  $K_d$  was  $6.7 \pm 0.3 \mu\text{M}$ . Fitting of the rate of the change (Figure 3) yielded an apparent  $k_{\text{on}}$  of  $2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$  ( $1.2 \times 10^8 \text{ M}^{-1} \text{ min}^{-1}$ ) and a  $k_{\text{off}}$  of  $4 \text{ s}^{-1}$  ( $240 \text{ min}^{-1}$ ), assuming a two-state model ( $K_d = 2 \mu\text{M}$ ). This  $k_{\text{on}}$  value is on the same order of magnitude of rate constants reported for P450 2A6,<sup>26</sup> much faster than seen for some other P450s for which productive binding probably involves multiple steps.<sup>51,52</sup>

**Product Release (step 9 of Figure 1).** Interaction of 12-OH lauric acid with P450 4A11 resulted in a shift of the basal high-spin iron component to a low-spin component, yielding a spectral change that was the opposite of that seen for the substrate lauric acid (or other fatty acids) and sometimes termed “reverse type I”<sup>36</sup> (Figure 4B). Titration with 12-OH lauric acid yielded an apparent  $K_d$  of  $5.1 \pm 2.1 \mu\text{M}$  (Figure 4D). Analysis of the kinetics of binding yielded an apparent  $k_{\text{on}}$  of  $2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$  ( $1.2 \times 10^8 \text{ M}^{-1} \text{ min}^{-1}$ ) and a  $k_{\text{off}}$  of  $1.3 \text{ s}^{-1}$  ( $240 \text{ min}^{-1}$ ), assuming a two-state model. The  $k_{\text{off}}$  rate is much faster than the overall rate of catalysis (Table 1). An experiment designed to detect a possible burst reaction was clearly negative (Figure 5), indicating that a rate-determining step does not occur after product formation.

**Reduction of Ferric P450 4A11.** Ferric P450 4A11 was reduced by NADPH-P450 reductase in the presence of the substrate lauric acid (50  $\mu\text{M}$ ), under anaerobic conditions. The rates measured at 390 and 418 nm (decreased absorbance) represent the reduction of the high- and low-spin components, respectively, and were nearly identical [ $340 \pm 10$  and  $280 \pm 25 \text{ min}^{-1}$ , respectively, for the fast phase (Figure 6)]. In both cases, a slower second phase ( $5 \pm 1$  and  $6 \pm 1 \text{ min}^{-1}$ , respectively) followed.

P450 reduction experiments are usually monitored at 450 nm, recording the formation of the  $\text{Fe}^{2+}$ –CO complex. In this case (Figure 6), the kinetics of the fast phase (at 454 nm) were much slower than those measured at 390 or 418 nm, i.e.,  $48 \pm 3 \text{ min}^{-1}$ . This apparent discrepancy was shown to be due to an unexpectedly slow rate of CO binding (Figure 6D). At 50% (v/

**Figure 3.** Rates of binding of lauric acid and 12-OH lauric acid to P450 4A11. The samples were mixed in a stopped-flow spectrophotometer as described in Experimental Procedures. Because of the low  $K_d$  values, estimates were made by fitting the reaction of 2  $\mu$ M P450 4A11 and 2  $\mu$ M ligand using DynaFit. Panels A and B show the changes in signals in opposite directions for the binding of lauric acid, and panel C shows the binding of 12-OH lauric acid. The red lines are fits to the rate constants that follow, using DynaFit (Supporting Information). (A and B) Lauric acid:  $k_{on} = 2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$  or  $1.2 \times 10^8 \text{ M}^{-1} \text{ min}^{-1}$ , and  $k_{off} = 4.0 \text{ s}^{-1}$  or  $240 \text{ min}^{-1}$ . (B) 12-OH lauric acid:  $k_{on} = 2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$  or  $1.2 \times 10^8 \text{ M}^{-1} \text{ min}^{-1}$ , and  $k_{off} = 1.3 \text{ s}^{-1}$  or  $78 \text{ min}^{-1}$ .

v) CO (nominal aqueous concentration of  $\sim 500 \mu\text{M}$ ), the rate measured for the binding of CO was  $66 \text{ min}^{-1}$  ( $1.1 \text{ s}^{-1}$ ), corresponding to a second-order rate constant of  $\sim 2 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$  ( $1.2 \times 10^5 \text{ M}^{-1} \text{ min}^{-1}$ ), much less than expected for a diffusion-controlled reaction. Other P450s have shown high rate constants; e.g., for P450 101A1, a reported rate constant is  $5 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ , 50-fold higher.<sup>53</sup>

**Transfer of the Second Electron to the P450 4A11  $\text{Fe}^{2+}\text{-O}_2$  Complex from  $b_5$ .** P450 4A11 reactions are stimulated  $\sim 2$ -fold by  $b_5$  (Figure 2), as reported previously by others.<sup>17</sup> Apo- $b_5$ , devoid of heme, was not able to stimulate P450 4A11 lauric acid hydroxylation (Figure S1 of the Supporting Information). These results indicate that  $b_5$  functions in this case by transferring an electron to the  $\text{FeO}_2^{2+}$  entity (Figure 1).

$b_5$  was photochemically reduced and mixed with air, being oxidized at a rate of  $0.11 \text{ min}^{-1}$  at  $23^\circ\text{C}$  (data not shown). The experiment was repeated in the presence of photochemically reduced P450 4A11. A separate experiment with reduced P450 4A11 alone (reduction verified spectrally before introduction into the stopped-flow syringes) did not show a clear  $\text{FeO}_2^{2+}$ –

complex spectrum. When the mixture of reduced P450 4A11 and  $b_5$  was mixed with air, the  $b_5$  was oxidized at a rate of  $0.8 \text{ min}^{-1}$  (at  $23^\circ\text{C}$ ), as judged by absorbance measurements at 390 and 424 nm (Figure 7). These studies indicate that the rate of  $b_5$  electron transfer to the  $\text{FeO}_2^{2+}$  form of P450 4A11 is relatively slow ( $\sim 1 \text{ min}^{-1}$  at  $23^\circ\text{C}$ ), consistent with the modest enhancement (2-fold at  $37^\circ\text{C}$ ) of rates by  $b_5$  (Figures 2 and 7).

**C–H Bond Breaking and KIEs with Recombinant P450 4A11.** One approach to judging the influence of the rate of C–H bond breaking on the overall reaction is the use of KIEs.<sup>40,54,55</sup> Preliminary KIE studies with  $d_0$  and  $d_{23}$  (perdeutero) lauric acid suggested a relatively low KIE in noncompetitive (intermolecular) steady-state kinetic studies (Table 2). This was the case for both 12- and 11-hydroxylation (the latter accounting for  $<10\%$  of the product).

More detailed studies were conducted with 12- $d_3$ -lauric acid (Figure 8), in which C–H bonds are substituted with deuterium only at the major site of hydroxylation, i.e., C–H bond breakage. These experiments also yielded low KIEs in noncompetitive, intermolecular experiments (Table 2). Inverse KIEs (i.e.,  $<1$ ) were also observed for the minor product, 11-OH lauric acid (Table 2).

The low KIEs could be used to infer rapid C–H bond cleavage. However, the observed “metabolic switching”<sup>56</sup> (from 12- to 11-hydroxy product) is not consistent with this view. For a more appropriate analysis of the KIE, it is necessary to know the intrinsic KIE ( $^Dk$ ) for C–H bond cleavage at carbon 12.

One approach to estimating  $^Dk$  is with the use of an “isotopically sensitive branching” method, which can be applied when a minor product is also produced.<sup>57,58</sup> In the literature, this method has been applied to  $k_{cat}$  ( $^DV$ ) results (actually applied to single-value results measured at high substrate concentrations).<sup>57,58</sup> With the knowledge that the reaction is irreversible and ignoring secondary KIEs, Jones et al.<sup>58</sup> transformed eq 1 (which is eq 10 of ref 57)

$$(k_H/k_D)_{\text{obsd}} = \frac{k_H/k_D + k_H/(k_{-1} + k_3)}{1 + k_H/(k_{-2} + k_3)}$$

into eq 2<sup>58</sup>

$$(k_H/k_D)_{\text{obsd}} = [k_H/k_D + (\text{ratio of primary C–H product}) / (\text{secondary C–H product})] / [1 + (\text{ratio of primary C–H product}) / (\text{secondary C–H product})]$$

which when transposed to the P450 4A11 system with the nomenclature used here gives

$$^DV = [^Dk + (12\text{-OH lauric acid}) / (11\text{-OH lauric acid})] / [1 + (12\text{-OH lauric acid}) / (11\text{-OH lauric acid})]$$

and in this case (Table 2) leads to

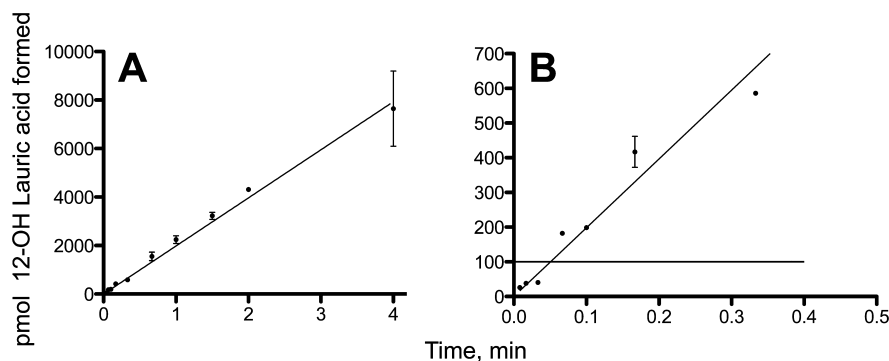

$$2.3 = (^Dk + 14.5/1.8) / (1 + 14.5/1.8)$$

and  $^Dk = 13$ , the apparent intrinsic isotope effect, which is consistent with the large degree of metabolic switching (Table 2).

An alternate approach to estimating  $^Dk$  comes from Northrop,<sup>40</sup> using noncompetitive intramolecular KIEs ( $V/K$ ) and the relationship

**Figure 4.** Binding of lauric acid and 12-OH lauric acid to P450 4A11. (A) Lauric acid. (B) 12-OH Lauric acid. The  $K_d$  values for (C) lauric acid and (D) 12-OH lauric acid were  $6.7 \pm 0.3$  and  $5.2 \pm 2.1$   $\mu\text{M}$ , respectively. The binding parameters and SE were calculated from the single titrations shown in the plots, utilizing GraphPad Prism.

**Figure 5.** Lack of burst kinetics for P450 4A11-catalyzed  $\omega$ -hydroxylation of lauric acid. The assays were conducted with 100 pmol of P450 at 37 °C. (A) Conventional steady-state kinetics. (B) A rapid quench apparatus was used for short time intervals. The resulting data points are fit to rates using linear regression analysis. The horizontal line in panel B (100 pmol of product, i.e.,  $y$ -axis 100) is drawn to represent a single turnover of the enzyme.

$$[\text{D}(V/K) - 1]/[\text{T}(V/K) - 1] = (\text{D}k - 1)/(\text{T}k - 1)$$

using the nomenclature applied in this paper. We used MS analysis of the 12-OH lauric acid obtained from an incubation of 12- $d_1$ -lauric acid to determine a  $\text{D}(V/K)$  value of  $1.9 \pm 0.1$  ( $n = 3$ ). 12- $t_1$ -Lauric acid was prepared, and the ratio of tritium in the  $^3\text{H}_2\text{O}$  (from cleavage of the C–T bond) and  $[^3\text{H}]$ -12-OH lauric acid (cleavage of the C–H bond, divided by 2 for statistical reasons) was used to calculate a  $\text{T}(V/K)$  of  $3.5 \pm 0.1$  ( $n = 3$ ). Solving the equation and using a set of tables,<sup>39</sup>  $\text{D}k \sim 20$  and  $\text{T}k \sim 77$  (with a 14% SE).

The overall conclusion is that the 12-hydroxylation reaction has a relatively high intrinsic KIE,  $\text{D}k$ , of 10–20, typical of a number of P450s.<sup>23,25,59,60</sup> The observed (noncompetitive) KIE is attenuated but still significant in the steady-state kinetic results.

Competitive (intermolecular) KIEs were measured using an equimolar mixture of  $d_0$ - and  $d_{23}$ -lauric acid. The KIE for 12-hydroxylation was  $1.3 \pm 0.2$ , and the KIE for 11-hydroxylation was  $0.9 \pm 0.1$ .

**KIEs with Human Liver Microsomes.** P450 4A11 is a major lauric acid  $\omega$ -hydroxylase in liver microsomes, and we compared some of the KIE results, in this context of a more functional biological system. Only the work with  $d_0$ - and 12- $d_3$ -lauric acid was done (Figure 9). As in the case of purified P450 4A11, 11-hydroxylation was a minor reaction. From the results obtained here, the following values were calculated for 12-hydroxylation:  $\text{D}V = 1.2 \pm 0.2$ , and  $\text{D}(V/K) = 2.1 \pm 0.7$ . For 11-hydroxylation, the values were as follows:  $\text{D}V = 1.0 \pm 1.2$ , and  $\text{D}(V/K) = 0.15 \pm 0.26$ . The high SEs in the 11-hydroxylation results are due to the low rates observed with the  $d_0$  substrate, but the graph conveys the conclusion that the patterns (low KIE for 12-hydroxylation, strong metabolic switching to 11-hydroxylation) are similar to those with the purified enzyme system.

## DISCUSSION

Although human P450 4A11 has been the subject of considerable interest because of its potential role in hypertension,<sup>18</sup> there is no crystal structure and relatively little work

**Figure 6.** Reduction of ferric P450 4A11 and CO binding to  $\text{Fe}^{2+}$  P450 4A11. The samples were mixed in a stopped-flow spectrophotometer as described in Experimental Procedures. Traces are shown for reactions that included  $100 \mu\text{M}$  lauric acid. The red lines show fits to the estimated rates, using the OLIS software (parallel first-order rates in panels A–C and pseudo-first-order rate in panel D). (A) The rates of the fast phase were  $0.80 \pm 0.05 \text{ s}^{-1}$  and  $48 \pm 3 \text{ min}^{-1}$  and of the slow phase  $0.080 \pm 0.01 \text{ s}^{-1}$  and  $4.8 \pm 0.6 \text{ min}^{-1}$ . (B) The rates of the fast phase were  $5.7 \pm 0.2 \text{ s}^{-1}$  and  $340 \pm 10 \text{ min}^{-1}$  and of the slow phase  $0.080 \pm 0.01 \text{ s}^{-1}$  and  $4.8 \pm 0.6 \text{ min}^{-1}$ . (C) The rates of the fast phase were  $4.7 \pm 0.4 \text{ s}^{-1}$  and  $280 \pm 24 \text{ min}^{-1}$  and of the slow phase  $0.10 \pm 0.02 \text{ s}^{-1}$  and  $6.0 \pm 1.2 \text{ min}^{-1}$ . (D) For binding of CO to  $\text{Fe}^{2+}$  P450 4A11, the rate was  $1.1 \pm 0.1 \text{ s}^{-1}$  or  $66 \pm 7 \text{ min}^{-1}$ .

**Figure 7.** Reoxidation of ferrous  $b_5$  in the presence of P450 4A11  $\text{Fe}^{2+}$  and  $\text{O}_2$ . P450 4A11 ( $2.0 \mu\text{M}$ ), in the presence of  $75 \mu\text{M}$  *L*- $\alpha$ -dilauroyl-*sn*-glycero-3-phosphocholine,  $1.0 \text{ mM}$  tris(2-carboxyethyl)phosphine,  $2.0 \mu\text{M}$   $b_5$ ,  $100 \mu\text{M}$  lauric acid, and  $1.0 \mu\text{M}$  5-deazaflavin [in  $200 \text{ mM}$  Tris-acetate buffer (pH 7.4) containing  $10 \text{ mM}$  EDTA], was deoxygenated and then photo-reduced ( $500 \text{ W}$  lamp,  $3 \times 1 \text{ min}$ ) (verified using steady-state spectroscopy). The sample was introduced into the stopped-flow spectrophotometer and mixed with an equal volume of air-saturated  $100 \text{ mM}$  potassium phosphate buffer ( $23^\circ\text{C}$ ). Analysis of the data yielded first-order rates of  $0.079 \pm 0.010 \text{ min}^{-1}$  at  $409 \text{ nm}$  and  $0.080 \pm 0.013 \text{ min}^{-1}$  at  $424 \text{ nm}$ . When the rate of reoxidation of photochemically reduced  $b_5$  was analyzed under these conditions in the absence of P450 4A11, the reoxidation rate was  $0.11 \text{ min}^{-1}$  (data not shown).

has been published regarding its mechanism or, for that matter, any of the subfamily 4A P450s.<sup>13,15,17,22</sup> In this study, we considered a prototypic  $\omega$ -hydroxylation reaction catalyzed by P450 4A11 and what steps are at least partially rate-limiting in catalysis. We conclude that at least two steps in the catalytic cycle, steps 4 and 7, contribute to the overall steady-state rate. Steps 1, 2, and 9 were shown to be rapid and because of this do not affect the overall rate.

The binding and release of ligands, at least the substrate and product, appear to be faster and simpler than in the case of some of the other human P450s, e.g., 3A4,<sup>51,61</sup> 1A2,<sup>62</sup> and 19A1.<sup>52</sup> These P450s appear to have more complex, multi-phasic kinetics, and movement to the proximity of the iron is a slower, more complex process, which in some of the cases involves multiple ligands being present.<sup>62,63</sup> The differences may be due to the size of the active site, although this is still unknown in the case of P450 4A11. The fatty acid arachidonic acid is almost twice as long as lauric acid and is still a substrate.<sup>18</sup> It is possible that P450 4A11 has a much more rigid site, but this is also a matter of speculation. What is known is that subfamily 4A P450s have restricted active sites, which is somewhat intuitive as evidenced by their proclivity to oxidize terminal methyl groups, an energetically unfavorable reaction. Evidence of the oxygenation of even a chlorine atom positioned at the  $\omega$  position has been presented.<sup>16</sup>

$b_5$  stimulates a number of P450s in an “allosteric” mode, instead of electron transfer.<sup>64</sup> One can speculate that  $b_5$  may act in this mode because of its ability to bind and restrict motion of a flexible protein. P450s 2E1 and 2A6 also require electron transfer for the stimulatory effect of  $b_5$ ,<sup>26,64</sup> and these enzymes are known to have relatively rigid, compact structures.<sup>65,66</sup>

The reduction of P450 4A11 is relatively rapid in the catalytic cycle (Figure 6). Binding of lauric acid clearly shifts the iron equilibrium toward the high-spin form (Figure 4). However, both high- and low-spin P450 4A11 iron showed similar rates of reduction by NADPH-P450 reductase (Figure 6). Although the view has been expressed that a shift in oxidation–reduction potential is associated with substrate binding and spin-state changes,<sup>67</sup> equivalent rates of reduction of high- and low-spin P450 iron have been shown here (Figure 6) and for P450 1A2.<sup>45</sup>

Table 2. KIEs for Lauric Acid 12- and 11-Hydroxylation

| lauric acid <sup>a</sup> | $k_{\text{cat}}$ (min <sup>-1</sup> ) | $K_m$ (μM) | $k_{\text{cat}}/K_m$ (μM <sup>-1</sup> min <sup>-1</sup> ) | $D_V$       | $D(V/K)$    |
|--------------------------|---------------------------------------|------------|--|-------------|-------------|
| 12-Hydroxylation         |                                       |            |  |             |             |
| $d_0$                    | 12.1 ± 0.6                            | 11 ± 2     | 1.1 ± 0.2  |             |             |

| $d_0$                    | 14.5 ± 0.7                            | 19 ± 3     | 0.76 ± 0.12  |             |             |
| $d_3$                    | 6.3 ± 0.1                             | 10 ± 1     | 0.63 ± 0.06  | 2.3 ± 0.1   | 1.2 ± 0.2   |
| 11-Hydroxylation         |                                       |            |  |             |             |
| $d_0$                    | 0.77 ± 0.05                           | 3.0 ± 1.0  | 0.25 ± 0.08  |             |             |
| $d_{23}$                 | 0.55 ± 0.03                           | 4.4 ± 1.0  | 0.13 ± 0.04  | 1.4 ± 0.1   | 2.0 ± 0.7   |
| $d_0$                    | 1.8 ± 0.2                             | 27 ± 7     | 0.06 ± 0.02  |             |             |
| $d_3$                    | 9.0 ± 0.3                             | 16 ± 2     | 0.56 ± 0.07  | 0.18 ± 0.02 | 0.11 ± 0.04 |

<sup>a</sup>Products were measured using the GC method. The SE estimates are derived from within each hyperbolic fit of plots of the reaction rate ( $v$ ) vs substrate concentration ( $S$ ) in GraphPad Prism, and the SE in the quotients is the fractional square root of the sum of the fractional squares of the SE in both operators. The variation in the  $K_m$  values for 11-hydroxylation is attributed to the low rate for this reaction; e.g., see the plot for the microsomal reaction in Figure 9.

Figure 8. Effect of deuteration at carbon 12 on product distribution due to a KIE. The bottom traces show GC traces with  $d_0$ -lauric acid (with or without NADPH), and the top traces show the corresponding experiment with 12- $d_3$ -lauric acid (100 μM in each case), with or without NADPH. The peaks identified as 11- and 12-OH lauric acid are designated with arrows, as is the internal standard 10-OH lauric acid.

The slow rate of CO binding (Figure 6D) was unexpected; we have not noticed this previously with other mammalian P450s.<sup>26,33,45,52,68</sup> The reason for the slow binding is unknown. Some plant P450s have low CO affinity,<sup>69</sup> but this is a case of a slow  $k_{\text{on}}$  rather than a fast  $k_{\text{off}}$ . There can be speculation about restricted access to the heme iron, based on the work with a rat orthologue.<sup>66</sup> One question that arises is whether  $O_2$  access is also restricted. However, we were unable to detect an  $Fe^{2+}-O_2$  complex in our work (Figure 7). If the rate of  $O_2$  access were similar to that of CO ( $\sim 60 \text{ min}^{-1}$ ), it would still be faster than overall turnover but could begin to contribute in that the overall rate of  $O_2$  consumption is  $28 \text{ min}^{-1}$  for the enzyme (Table 1).

There has been considerable interest in identifying rate-limiting steps in P450 reactions since research in the field began.<sup>70–72</sup> KIEs were used in some early work,<sup>70,71,73</sup> although in many of these cases, it is not possible to interpret whether the finding of a significant primary KIE meant that C–H bond breaking contributed to a change in rate. Today there is no

consensus regarding a single, unified rate-limiting step in all P450 reactions. However, in several cases, there is evidence that certain steps are limiting (this varies depending upon the experimental system and the particular oxidation reaction being studied). In the human P450 7A1-catalyzed  $7\alpha$ -hydroxylation of cholesterol, reduction of the ferric iron was concluded to be the most rate-limiting step.<sup>27</sup> With some P450s, there is evidence that  $b_5$  stimulates reactions, and if apo- $b_5$  does not, then presumably  $b_5$  is donating an electron to the  $Fe^{2+}-O_2$  complex to facilitate the reaction (i.e., that step must be limiting).<sup>64</sup> This is the case with at least some of the catalyses of human P450 2A6<sup>26</sup> and 2E1.<sup>64</sup> With human P450 2E1 and the oxidation of ethanol, the most rate-limiting step follows product formation,<sup>38,74</sup> giving rise to burst kinetics and a KIE on  $K_m$ . For several P450s, high KIE values are observed in non-competitive experiments, e.g., P450s 1A2,<sup>25</sup> 2A6,<sup>26</sup> and 2D6,<sup>75</sup> indicative of major C–H bond breaking limitation on rates.

KIE studies can be complicated in that enzymatic reactions are complex and include multiple steps, only one of which is

**Figure 9.** KIE patterns for lauric acid hydroxylation in human liver microsomes. The methods are described in Experimental Procedures. Assays were conducted in duplicate, and the points indicate the means  $\pm$  the range. As described in Experimental Procedures, parameters were estimated using hyperbolic fits in GraphPad Prism, and SE values are from those fits. Rates are expressed on a milligram protein basis. The following parameters were obtained: for  $d_0$  12-hydroxylation,  $V_{\max} = 1.10 \pm 0.06$  nmol of product formed  $\text{min}^{-1}$  (mg of protein) $^{-1}$  and  $K_m = 48 \pm 7$   $\mu\text{M}$ ; for  $d_3$  12-hydroxylation,  $V_{\max} = 0.94 \pm 0.11$  nmol of product formed  $\text{min}^{-1}$  (mg of protein) $^{-1}$  and  $K_m = 86 \pm 22$   $\mu\text{M}$ ; for  $d_0$  11-hydroxylation,  $V_{\max} = 0.96 \pm 1.18$  nmol of product formed  $\text{min}^{-1}$  (mg of protein) $^{-1}$  and  $K_m = 1890 \pm 2530$   $\mu\text{M}$ ; for  $d_3$  11-hydroxylation,  $V_{\max} = 0.96 \pm 0.12$  nmol of product formed  $\text{min}^{-1}$  (mg of protein) $^{-1}$  and  $K_m = 288 \pm 55$   $\mu\text{M}$ .

generally involved in C–H bond cleavage.<sup>40,76</sup> Two kinds of KIE measurements are particularly relevant for estimating the contribution of C–H bond cleavage to an overall reaction rate: (i) the intrinsic KIE ( $^Dk$ ), which is an estimate for the KIE of the individual chemical C–H bond breaking step, and (ii) the noncompetitive intermolecular KIE, preferably  $^D(V/K)$ , which expresses the degree to which the  $^Dk$  is expressed. A low  $^D(V/K)$  value coupled with a high  $^Dk$  indicates that C–H bond breaking is not a very rate-limiting step in the overall reaction.<sup>77</sup> While measurement of  $^D(V/K)$  (and  $^DV$ ) (Table 2) is generally straightforward (if a suitable deuterated substrate is available), estimating  $^Dk$  for a reaction may be more complex because of “masking” that results from “commitment to catalysis” and related factors.<sup>77</sup>

Two main approaches to estimating  $^Dk$  have been used, the isotopically sensitive branching method<sup>57</sup> and the tritium isotope method (“Northrop method”).<sup>39,40</sup> The former can be applied when there is metabolic switching to an alternate product,<sup>56</sup> as in the case of  $\omega$ -1 hydroxylation here (Figure 8). The Northrop approach requires the comparison of  $^D(V/K)$  and  $^T(V/K)$  with similarly labeled substrates, which is possible here through chemical synthesis, and had been previously applied to other P450 reactions.<sup>60,78</sup> Both approaches yielded high values for  $^Dk$ , 13 and  $\sim 20$ , respectively. These values may be compared with the low expressed values of  $^DV$  and  $^D(V/K)$  observed for  $\omega$ -hydroxylation (1.2–2.3) in Table 2, indicating weak expression of a high intrinsic KIE. The situation is similar to that of P450 3A4-catalyzed testosterone  $6\beta$ -hydroxylation, with a high  $^Dk$  value established by Northrop’s method but a low observed  $^D(V/K)$ .<sup>60</sup>

The concept of a relatively low KIE in typical experiments but a high intrinsic KIE is not novel, having been revealed by Miwa, Lu, and their associates with ethoxycoumarin reactions.<sup>78</sup> One question that can be asked is what the relationship is between the magnitude of a primary KIE (for a noncompetitive intermolecular comparison) and the contribution of a rate-limiting step.<sup>23</sup> The situation is complex with a P450 system, in that some of the steps (Figure 10) are reversible and there are also steps that result in the production of reduced and partially reduced oxygen species (Table 1). In previous work with another rabbit P450 1A2, kinetic modeling suggested that a KIE of 8.4 was related to an estimated 11-fold change in the rate of the C–H bond cleavage step due to deuteration,<sup>25</sup> but relating a smaller KIE to an actual ratio is more difficult. With the information available here, we can conclude that only step 7 (Figures 1 and 10) contributes at least partially to limiting rates of hydroxylation.

In conclusion, we have analyzed the P450 4A11 catalytic mechanism and found two steps that appear to be partly rate-limiting, steps 4 and 7 (Figure 10). Steps 1, 2, and 9 all appear to be too fast to be rate-limiting. We have not measured rates of steps 3, 5, 6, and 8, which are all more difficult or not even possible. Efforts to characterize a rate-limiting step by the

**Figure 10.** Generalized catalytic P450 scheme with measured rates or rate constants.

nature of the accumulating spectral species in the steady state were unsuccessful because of the dominance of ferrous  $b_5$  in the spectra (data not presented). Another point that should be made, in closing, is that the overall flux of the catalytic cycle (Figures 1 and 10) is a function of not only forward rates but also the leakiness of the system and abortive reduction of oxygen (Figure 10 and Table 1), which can undermine the catalytic efficiency of the system.
